Abstract: This study investigated some gross anatomical measurements of the head region of the cattle without any apparent skeletal disorders and their clinical value for regional anesthesia. Thirty Iranian native cows were used and a total of 15 anatomical measurements were done in the upper jaw and mandibles. The distances from the base of horn to caudal border of orbit, to mid-level of dorsal arch of orbit and to rostral border of orbit were 7.9 cm, 10.4 cm and 14.6 cm, respectively. The distances from facial tuberoses to the infra-orbital canal and from the latter to the root of the alveolar tooth were 2.8 cm and 2.5 cm, respectively. The length and height of the mandibles were 27.4 cm and 15.88 cm, respectively. The distances from the lateral alveolar root to mental foramen and from the mental foramen to caudal mandibular border were 5.7 cm and 23.8 cm, respectively. The distances from mandibular foramen to the base of mandible as well as from caudal border of mandible to below of the mandibular foramen were 5.2 cm and 2.9 cm, respectively. The distances from the base of mandible to condyloid fossa and from the latter to the maximum height of mandible were 8.5 cm and 5.4 cm, respectively. The distance from caudal border of mandible to mandibular foramen and from the latter to mandibular angle were 1.7 cm and 4.84 cm, respectively. These data as important landmarks are discussed with regard to their application to clinical maneuvers around the head of the Iranian native cows such as regional anesthesia during dental extraction, dehorning and treating horn injury.

Key words: Gross Anatomy · Head · Iranian Native Cattle · Regional Anesthesia.

INTRODUCTION

A basic knowledge of skull anatomy is important in the practice of veterinary medicine. It has been demonstrated that osteometric examination of bones provides significant insights into intra-species as well as interspecies differences in the animals [1]. In addition, the anatomical evaluations of animals show considerable variation with respect to breed, age, sex, nutritional situation and environmental factors among others [2].

Gross anatomical surveys on the head region are not only reflect contributions of genetic and environmental components to individual development and describe genetic and ecophenotypic variation, but also are foundations of the clinical and surgical practices [3, 4].

Furthermore, the applied anatomy of the head region is very important because of such vital organs and structures as the brain, tongue, eyes as well as ears, teeth, nose, lips, horn and skull. Thus the head is needed for coordinating the body as well as for deglutition, olfaction and defense [5, 6]. Similarly, the directions of the cranial nerves and their passages from different foramina in the skull are of clinical importance in regional anesthesia around the head [5, 7].

Cattle were domesticated about 10 000 years ago and, as for most other domestic animal species, domestication was probably limited to a few regions including the Near East and Asia [8]. Because of economic values of cows especially for their meat, milk and other dairy products; cattle are raised as livestock [9] and there has been an increasing interest and necessity to have more information concerning the applied anatomy of the head region of this specie. Some previous studies had been done on the heads of domestic animals including the cow, buffaloes, horse, sheep and goat [3, 6, 10, 11]. However, data is very little about osteometric measurements of head
region in the Iranian native cattle and its clinical importance in regional anesthesia. Therefore the current work was taken to provide information on clinically important parameters that may aid regional anesthesia of the head.

MATERIALS AND METHODS

To make the present work, a total of thirty Iranian native cattle aged between 4-6-year-old were used. The live animals were first selected during ante mortem examination at Ilam abattoir based on parameters of apparent good health and no skeletal disorders. After slaughter, the heads were severed at the occipito-atlantal joint, purchased and processed in the veterinary anatomy laboratory of Ilam University using the boiling maceration techniques for skeleton preparation that have been reported by Simoens et al. [12]. The main steps in skull skeleton preparing briefly are following:

- On the working day, frozen cow head were allowed to thaw.
- Skin and most of the muscles were separated and eyes were enucleated.
- Heads were heated to over 80 ºC for at least 1 hour in solution of anionic surfactant (detergent) and soap chips.
- Muscles of boiled heads were separated with the aid of forceps and scalpel in running water.
- Further separation of muscles and ligaments from the skulls was done after left in detergent water at least 20-30 minutes.
- Separation of remaining muscles and ligaments from the skull was done after left in 1% sodium hypochlorite solution for at least 24 hours.
- After that, the skulls were left in the above solution, for 48-72 hours with solution, being changed at least twice and clean in running tap water.
- The skulls were then left to dry.

A total of 15 morphometric measurements were done in the upper jaw and mandibles using scale, thread and digital calipers and the results were presented as means ± SD in Table 1. These morphometric parameters of the upper and lower jawbones of the Iranian native cattle’s skulls are defined below and shown in Figs. 1- 4.

- The base of horn to caudal border of orbit: The distance between the base of the horn to caudal most border of the orbit.
- The base of horn to mid-level of dorsal arch of orbit: The distance between the bases of the horn to the mid-level of dorsal arch of the orbit.
- The base of horn to rostral border of orbit: The distance between the base of the horn to rostral most border of the orbit.

Fig 1: Skull of the Iranian native cattle; lateral view. A: The base of horn to caudal border of orbit, B: The base of horn to mid-level of dorsal arch of orbit, C: The base of horn to rostral border of orbit. D: Facial tuberoses to infra-orbital canal, E: Infra-orbital canal to root of alveolar tooth.

Fig 2: Mandible of the Iranian native cattle; lateral view. F: Mandibular length, G: Lateral alveolar root to mental foramen, H: Mental foramen to caudal mandibular border.

- Facial tuberosity to infra-orbital canal: From the level of the most lateral bulging of the facial tuberosity to the mid level of the infra-orbital canal.
- Infra-orbital canal to root of alveolar tooth: Measurement is taken vertically from the mid-level of the in infra-orbital canal to the root of the alveolar tooth.
- Mandibular length: From the level of the cranial extremity of the alveolar root of the incisor to the level of the caudal border of the mandible.
RESULTS

In the current study, the distance from the base of the horn to caudal border of orbit, to mid-level of dorsal arch of orbit and to rostral border of orbit were 7.9 cm, 10.4 cm and 14.6 cm, respectively. The distance from facial tuberoses to the infra-orbital canal and from the latter to the root of the alveolar tooth was 2.8 cm and 2.5 cm in the Iranian native cattle (Figure 1, Table 1). The distance between the root of the teeth and the foramen was 2.5 cm. The distance between lateral alveolar roots to mental foramen was 5.7 cm (Figure 2, Table 1). The mandibular length and height in the Iranian native cattle are inserted in the Table 1. In the Iranian native cattle, the mandibular length and also the maximum mandibular height were 27.4 cm and 15.88 cm, respectively. The caudal border of the mandible to bellow of the mandibular foramen was 2.9 cm in the Iranian native cattle (Figure 3). The distance from the caudal border of mandible to the level of mandibular foramen and from the latter to the border of mandibular angle was 1.7 cm and 4.84 cm, respectively.

DISCUSSION

Dehorning of cows is carried out to make handling of animals safer and reduce the incidence of damage to other livestock. Alternatively, for cow’s dehorning and similar surgeries; the corneal nerve supply must be blocked. Although there was not literature data on the horn morphometric indices with which comparison could be made but these data have clinical value in the nerve block purposes and also regional anesthesia during dehorning and treating of the horn injuries.

Literature review shows the nerve supply to the horn region in the cows is originated from the corneal branches of the lachrymal (zygomatico-temporal) nerve and this must be blocked prior to dehorning [13]. As the corneal branch of the lachrymal nerve is course dorsal on the dorso-lateral aspect of the orbit and distributed in the root of the horn [11], therefore the value of distance from the base of horn to caudal border of orbit is most beneficial for determining the appropriate side for injection of local anesthetic agents.

The distance from the infra-orbital canal to the root of the alveolar tooth were 2.5 cm in the Iranian native cattle (Figure 1, Table 1); while in the adult cows and buffaloes from Pakistan were 2.54 cm and 3.81 cm respectively [10].

The facial tuberoses is very prominent as a guide for tracking the infra-orbital nerve and necessary for the desensitization of the skin of the upper lip, nostril and face on that side of the level of the foramen, therefore the current findings are of clinical importance. The injection of local anesthetic agents within the canal via the infra-orbital foramen will also lead to analgesia of the incisor, canine and first two premolars. In the present work, the infra-orbital foramen was situated directly
dorsal to the first upper premolar tooth in Iranian native cattle where as in the adult cows from Pakistan [10]. This information together with the observed distance of 2.5 cm between the root of the teeth and the foramen would provide a major landmark to regional anesthesia involving the infra-orbital nerve in the Iranian native cows.

The distance between lateral alveolar roots to mental foramen was 5.7 cm (Figure 2, Table 1) which is a vital guide that will detect the location of the mental nerve for this regional nerve block in the Iranian native cattle. Although, there was not previous data on the alveolar root length with which comparison could be made. The injection of the local anesthetic drugs can be made in the rostral aspect of the mandibular canal through the mental foramen to mandibular nerve block in the mental zone. This will ensure the loss of sensation of the lower incisors, premolar and lower lip on the same side [7] during dental extraction and treatment of tooth injuries.

The mandibular length and height in the Iranian native cows (Table 1) were similar to the data reported for cattle of Pakistan [10]. By contrast, the mandibular length of 27.4 cm and maximum mandibular height of 15.88 cm in Iranian native cows were lower than the value obtained for buffaloes of Pakistan [10].

The caudal border of the mandible to bellow of the mandibular foramen (Figure 3) was 2.9 cm in the Iranian native cattle. Also, in the Iranian native cattle, the distance from the caudal border of mandible to the level of mandibular foramen and from the latter to the border of mandibular angle were 1.7 cm and 4.84 cm, respectively (Figures 3 and 4, Table 1). These data are necessary for achieving the regional anesthesia of the mandibular nerve and also have clinical importance for desensitization of all the teeth in lower jaw [7].

The current results will find consideration as reference values for Iranian native cows and will thus contribute to morphometric investigations. Although, to best knowledge of the authors, there is no literature data on the anatomical indices of the head region especially about horn’s applied anatomy in the Iranian native cattle with which comparisons could be made. In conclusion, the current findings are of clinical importance that will aid the regional anesthesia of the different nerves around the head especially during dental extraction, dehorning and treating horn injuries.
