# Computation of Makespan Using Genetic Algorithm in a Flowshop 

R. Pugazhenthi and M. Anthony Xavior

School of Mechanical and Building Sciences, VIT University, Vellore-632014, Tamilnadu, India

#### Abstract

This research paper addresses the scheduling problems with the primary objective of minimizing the makespan in a flow shop with ' N ' jobs through ' M ' machines. The EPDT (Heuristic approach) and BAT (Meta-Heuristic approach) heuristics are proposed to solve the flow shop scheduling problem in a modern manufacturing environment. These two algorithms are applied along with the Genetic Algorithm (GA) for the further improvement of results in achieving the minimal makespan. The performances of these newer heuristics are evaluated by solving the Taillard benchmark problems in MATLAB environment with various sizes of problems. The proposed GA applied EPDT heuristic and GA applied BAT meta-heuristic for the flow shop problems have been found very effective in solving scheduling problems and finding a better sequence which can reduce the makespan to a great extent. The improvement of EPDT and BAT were obtained by applying the GA yields superior results as well as these results also very close to upper bound than NEH results. The results of the heuristics are tested statistically by ANOVA and it shows that the GA applied heuristics gives a quality solution.

Key words: Genetic algorithm • Mutation • Crossover

## INTRODUCTION

A Permutation Flow Shop (PFS) is a shop design of machines arranged in series in which the jobs are processed in a same order without eliminating any machine. Generally, the following assumptions are considered in any flowshop environment,

- Pre-emption is not allowed. Once an operation is started on the machine, it must be completed before another operation can begin on that machine.
- Machines never break down and are available throughout the scheduling period.
- All processing time on the machine are known, deterministic, finite and independent of sequence of the jobs to be processed.
- All the machines are readily available for continuous assignment, without consideration of temporary unavailability such as breakdown or maintenance.
- Each job is processed through each of the ' $M$ ' machines once and only once. Also a job does not become available to the next machine until and unless processing of the current machine is completed.
- In-process inventory is allowed. If a next machine in the sequence needed by a job is not available, the job can wait and join the queue of that machine.

Here the scheduling is a vital task which involves organizing, choosing and timing resource used to carry out all the activities necessary to produce the desired output at the desired time, while satisfying a large number of time and relationship constraints among the activities and the resources [1]. This forces researchers to focus their efforts in developing an optimal solution for achieving minimum makespan with newer heuristics.

An algorithm was developed, for flowshop scheduling problems with ' N ' jobs through 2 machines [2]. The NP-completeness of the flow shop scheduling problems had been discussed by Quan-Ke Pan and Ling Wang in detail [3]. Palmer [4] was the first to propose a heuristic with a slope index procedure, which was an effective and simple methodology in tracing a better makespan.

A significant work in the development of an effective heuristic was discussed by CDS [5]. Their algorithm consists essentially in splitting the ' $M$ ' machine problem into a series of equivalent two-machine flow shop
problems and solving by Johnson's rule. Dannenbring [6] had developed a procedure called 'rapid access', which attempted to combine the advantages of Palmer's slope index and CDS procedures.

Stinson and Simith [7] had proposed a different approach called travelling salesman problem with two steps. The solution was found to be better than Palmer [8] and CDS methods, but with increased computational effort.

Since the problem is NP-hard, the meta-heuristics are required to solve effectively the industry size problems. Thus, the meta-heuristics with search techniques were developed to achieve the near optimal solutions for the PFS problems [9]. For applying a local search technique in a PFS, an initial solution is generated and then it applies a move mechanism to search the neighborhood of the current solution to choose the better one [10]. Schuster and Framinan [11] used the neighborhood search technique which was specially designed for flow shop problems. This technique yields better result compared to others. A step of local search starts with the current feasible solution $\mathrm{x} \in \mathrm{X}$ to which is applied a function $\mathrm{m} \in$ $\mathrm{M}(\mathrm{x})$ that transforms x into x , a new feasible solution $\left(x^{\prime}=m(x)\right)$. This transformation is called a move and $\left\{x^{\prime}: x^{\prime}\right.$ $\left.=\mathrm{m}(\mathrm{x}) ; \mathrm{x}, \mathrm{x}^{\prime} \in \mathrm{X} ; \mathrm{m} \in \mathrm{M}(\mathrm{x})\right\}$ is called the neighborhood of x .

These heuristics can be further improved by adding a sub-process called searching technique. There are many searching techniques, some of them are Particle Swam Optimization [12], two-phase subpopulation genetic algorithm (GA) [13], HAS [14], hybrid genetic algorithm [15].

Among these techniques, the hybrid genetic algorithm performances well [16]. There are various methods to improve the performance of the genetic algorithm. The first possibility is to implement the best configuration of the algorithm itself [17, 18]. Alternatively, we could add in other heuristics as sub-process of the genetic algorithm, called hybrid GA (HGA). The most popular forms of the hybrid GA are to incorporate one or more of hill climbing and/or neighborhood search [19].

This research paper aims to minimize the makespan of a permutation flowshop through the application of hybrid genetic algorithm in a heuristic and meta-heuristic approach.

## Methodologies

Method I: EPDT Heuristic: The heuristic distributes a higher class of exponential factor to the processing time of the job based on the machine it passes through.

This helps in developing a mathematical model which is determined from the advancement of a classical algorithm called 'slope index' algorithm.

The exponential value factor added to the job processing time is evaluated through the exponential equation [20], which gives an index value to the job. By sorting the index value of the jobs in descending order, an optimal sequence can be obtained.

## Algorithm:

Step 1: Let ' n ' number of jobs to be machined through ' m ' machines. It is assumed that all jobs are present for processing at time zero. And one job can run on one machine at a time without changing the machine order.

Step 2: The exponential index to be calculated using the exponential equation (1) for ' $n$ ' jobs.

$$
\begin{equation*}
y_{j}=\sum_{i=0}^{i=m-1}(2.61 * m-\exp (i)) * T_{j m-i} \tag{1}
\end{equation*}
$$

where,
$Y_{j}=$ Exponential index value for $\mathrm{j}^{\text {th }} \mathrm{job}$,
$\mathrm{m}=$ Number of machines
$\mathrm{T}_{\mathrm{j}(\mathrm{m}-\mathrm{i})}=$ Process time of $\mathrm{j}^{\text {th }}$ job under $(\mathrm{m}-\mathrm{i})^{\text {th }}$ machine

Step 3: Sort the exponential index in descending order.

Step 4: Based on the sorted order, the jobs to be sequenced.

Method II: BAT Heuristic: The newly proposed heuristic (BAT heuristic) is to find an optimal makespan using mathematical logics with local search technique [21].

## Algorithm

Step 1: Assign the processing time of ' N ' jobs in ' M ' machines. And frame the PFS problem N x M matrix.

Step 2: Calculate $\mathrm{a}_{\mathrm{ij}}$ and $\mathrm{b}_{\mathrm{ij}}$ values using the equations (2) and (3).
$a_{i j}=\sum_{i=1}^{k-1} P_{i j}$
$b_{i j}=\sum_{i=k+1}^{m} P_{i j}$

Step 3: Calculate Ti , Ai and Bi values using the equations (4), (5) and (6).
$T_{i}=\sum_{j=1}^{n} P_{i j}$
$\mathrm{A}_{\mathrm{i}}=\min \left(\mathrm{a}_{\mathrm{ij}}\right)$
$\mathrm{B}_{\mathrm{i}}=\min \left(\mathrm{b}_{\mathrm{ij}}\right)$
Step 4: Calculate the Si values for 'M' machines using the equation (7).
$\mathrm{S}_{\mathrm{i}}=\mathrm{T}_{\mathrm{i}}+\mathrm{A}_{\mathrm{i}}+\mathrm{B}_{\mathrm{i}}$
Step 5: Calculate the LB value for the N x M PFS problem using the equation (8).
$\mathrm{LB}=\max \left(\mathrm{S}_{\mathrm{i}}\right)$
Step 6: Identify the Z machine by the below stated condition in equation (9).
$\mathrm{Z}=\mathrm{k}$; if $\left(\mathrm{LB}==\mathrm{T}_{\mathrm{k}}+\mathrm{A}_{\mathrm{k}}+\mathrm{B}_{\mathrm{k}}\right)$
Step 7: Identify the pivot jobs ZA and ZB is using the condition stated in equation (10) and (11).
$\mathrm{ZA}=\mathrm{j}$; if $\left(\mathrm{A}_{\mathrm{k}}==\mathrm{a}_{\mathrm{kj}}\right)$
$\mathrm{ZB}=\mathrm{j}$; if $\left(\mathrm{A}_{\mathrm{k}}==\mathrm{b}_{\mathrm{kj}}\right)$
Step 8: Place the ZA and ZB pivoted jobs in the sequence under the condition, if the pivoted job is $\mathrm{ZA},(\mathrm{Z} \neq 1) \& \&$ $(\mathrm{ZA} \neq 1)$ then place the ZA at the beginning of the sequence. If the pivoted job is $\mathrm{ZB},(\mathrm{Z} \neq \mathrm{M}) \& \&(\mathrm{ZB} \neq \mathrm{N})$ then place the ZB at the end of the sequence.

Step 9: After the step 9 is successful, eliminate the ZA and ZB jobs from the $\mathrm{N} x$ M PFS problem.

Step 10: Apply local search technique by repeating the step 3 to step 10.

Step 11: Arrange the jobs in a sequence according to the pivoting conditions.

Genetic Algorithm (GA) for Flow Shop Scheduling: The genetic algorithm (GA) was proposed by John Holland [22]. However, it has become one of the well-known meta-heuristics after Goldberg [23]. The mechanism of the simple GA is demonstrated in a pseudo
code. Hybrid genetic algorithm (HGA) [24] is a method of searching an optimal solution based on an evolutionary technique which works with a population of solutions. In the proposed GA, a population of solutions was considered and the fitness of each solution was evaluated by using a problem specific objective function after crossover as well as mutation operations. Then the best solution was selected which ensured a better solution. The stages of GA are as follows [25].

## Pseudo Code for HGA:

Step 1: Initialize a population from the heuristic proposed sequence.

Step 2: Perform a crossover operation to get offspring based on the probability of crossover.

Step 3: Conduct a mutation based on the probability of mutation.

Step 4: Fitness evaluation for each individual using an objective function of minimum makespan.

Step 5: Randomly select the survived chromosome for the next generation using roulette wheel.

Chromosome representation- A solution to the N -job and M-machine problem was represented as a chromosome. A chromosome consists of ' M ' parts; each part corresponding to each machine and consisting of ' $n$ ' bits that represent the order of jobs on that machine.

Fitness function- It evaluated the performance measures to be optimized. A fitness value was found for each chromosome or schedule which was the weighted sum of makespan.

Initial population- The initial solution or a population plays a critical role in determining the quality of the final solution. The sequence from the heuristic is taken as initial solution.

Selection- The better chromosome is selected by comparing the parent and daughter chromosomes under each stage or spin.

Crossover- The crossover process was used to breed a pair of children chromosomes from a pair of parent chromosomes. The crossover operator randomly chooses a locus and exchanged the sub-sequences before and after that locus between two chromosomes. Thus two new children chromosomes were developed from two parent chromosomes by crossover.

Mutation- If a random number generated was less than the mutation probability and then mutation would be carried out. Here, the mutation was done by interchanging two bits of a chromosome selected at random.

## RESULTS AND DISCUSSION

Statistical Analysis Using Taillard Benchmark Problems: The benchmark problems proposed by Taillard [26] are tested against the newly proposed EPDT heuristic and BAT heuristic for the various sizes of the problems with $20,50 \& 100$ jobs through $5,10 \& 20$ machines. The results obtained from the MATLAB environment for the NEH heuristic, EPDT heuristic, GA applied EPDT heuristic [27, 28], BAT heuristic and GA applied BAT heuristic were compared and tabulated in Table 1 to 9 . The maximum relative deviation from the upper bound was calculated using the equation (12).

Maximum Relative Deviation (MRD) $=($ Makespan - upper bound)/makespan*100

From the Table 1 to 9 , it can be seen that the GA based EPDT and BAT heuristics are found improved
when compared with NEH heuristic and the MRD also shows the same. The Table 10 and Figure 1 shows the average results of Table 1-9.

From the Table 10, the average MRD to UB was calculated and it is shown in Table 11 and Figure 2. It is observed that the GA applied BAT heuristic was better compared to others with less computational instances.

Analysis of Variance (ANOVA): The ANOVA is carried out to check the three main hypotheses which are normality, homogeneity of variance and independence of residuals. The residuals resulting from the experimental data were analyzed and all three hypotheses could be accepted [29]. For example, the normality can be checked by the plot of the residuals. Here the One way ANOVA was carried out in MINITAB16 environment, considering the makespan reaching the Upper Bound of the NEH, EPDT, GA applied EPDT, BAT and GA applied BAT heuristics. This analysis has been made to determine the optimal noise level by "smaller as best" concept and the best significant level has been identified for the GA applied BAT heuristic from the Table 12 and has been shown that the p-value is 0.419 which is lesser than f -value of 0.98 , at $95 \%$ confidence level.

| BAT | 0 | 6.054 | 7.085 |
| GA BAT | -3.482 | -2.452 | 0 |

The results of heuristics by benchmark problem are evaluated based on mean and Standard Deviation of 90 values with a constraint of "smaller, the best" and it is shown in Table 13. Even the GA applied BAT was better compared to others, the mean and Standard Deviation of other heuristics are also closer to the best results so the BAT and GA applied EPDT also good in the level of optimal makespan compared to NEH. And once from this Table 13, it has been proved that the GA applied BAT heuristic is better in finding minimum makespan compared to others.

The Hsu's MCB (Multiple Comparisons with the Best) based on "smaller the best" is shown in Table 14. From the Table 14, the proposed GA applied BAT is minimum at all levels compared to others and it is represented graphically in Fig. 3.

The residual plots of NEH, EPDT, GA applied EPDT, BAT and GA applied BAT heuristics was shown in Fig. 4. From the Figure 4, the GA applied BAT performs well in all three hypotheses that are (i) the range of makespan is normally distributed, (ii) the result are unique and well fitted to the upper bound and (iii) the residuals are independent. Since all three hypotheses are achievable, the GA applied BAT is concluded to be acceptable.

## CONCLUSION

The newly proposed heuristics performed well in achieving the primary objective of minimizing the makespan. With the application of GA the EPDT and BAT heuristics are reduces the makespan compared to EPDT and BAT heuristics. This work was evaluated through a set of benchmark problems in MATLAB environment and compared with results of NEH. The maximum relative deviation (MRD) from the upper bound of the heuristics was examined. A statistical analysis tool called ANOVA (one way stacked) was used to evaluate the heuristics in MINITAB platform. By this analysis, it is noticed that the BAT, GA applied EPDT and GA applied BAT are lies equally in residual plot which are closer and better compared to NEH. Among these approaches, the GA applied BAT gained a $p$-value of 0.419 which is lesser than f-value and it satisfy all three hypotheses; so it is considered to be acceptable. The GA applied BAT yields about 0.5 MRD from the upper bound so it is superior in finding the minimal makespan than others heuristics.
